ABSTRACT

Rapid development of diverse computer architectures and hardware accelerators caused that designing parallel systems faces new problems resulting from their heterogeneity. Our implementation of a parallel system called KernelHive allows to efficiently run applications in a heterogeneous environment consisting of multiple collections of nodes with different types of computing devices. The execution engine of the system is open for optimizer implementations, focusing on various criteria. In this paper, we propose a new optimizer for KernelHive, that utilizes distributed databases and performs data prefetching to optimize the execution time of applications, which process large input data. Employing a versatile data management scheme, which allows combining various distributed data providers, we propose using NoSQL databases for our purposes. We support our solution with results of experiments with our OpenCL implementation of a regular expression matching application.

KEYWORDS

Parallel Computing, High Performance Computing, Heterogeneous Environments, NoSQL, OpenCL

1. INTRODUCTION

The market of electronic hardware is developing in extreme pace, making sophisticated computing devices accessible to households. Research and development departments of hardware manufacturing companies compete in designing new architectures and accelerators. HPC (High Performance Computing) systems no longer can be considered as sets of very expensive devices forming a cluster, physically installed in one room. The HPC field has to deal with increasing heterogeneity of the systems and it should be taken into account that the parallelization is performed on many levels. We should be able to combine concepts as Grid Computing [1], GPGPU [2] and Volunteer Computing [3] into one multi–level parallel design.

Our parallel processing framework, KernelHive [13] is able to perform parallel computations on a set of distributed clusters containing nodes with different types of computing devices. We

Natarajan Meghanathan et al. (Eds) : ICCSEA, SPPR, VLSI, WiMoA, SCAI, CNSA, WeST - 2014
pp. 09–19, 2014. © CS & IT-CSCP 2014 DOI : 10.5121/csit.2014.4709

presented the KernelHive system and its performance capabilities in [4] and proposed an execution optimizer focusing on energy efficiency in [5]. Within this article, we add data intensity capabilities to the KernelHive system. For this purpose we propose MongoDB [6] database as a backend. For our experiments, we use our solution to the regular expression matching problem [7].

2. PROBLEM FORMULATION

From the parallelization point of view, the spectrum of computational problems in general can be structured as shown in Figure 1. The parallelization process requires dividing the problem into subproblems, solving them independently by parallel processes and finally merging the results. Certain problems require only partitioning the input data into chunks, which are processed indepentently. Problems of this type are called embarassingly parallel and on Figure 1 are located in the compute intensive corner. Until this work, the KernelHive system was dealing only with this type of problems (e.g. breaking MD5 hashes).

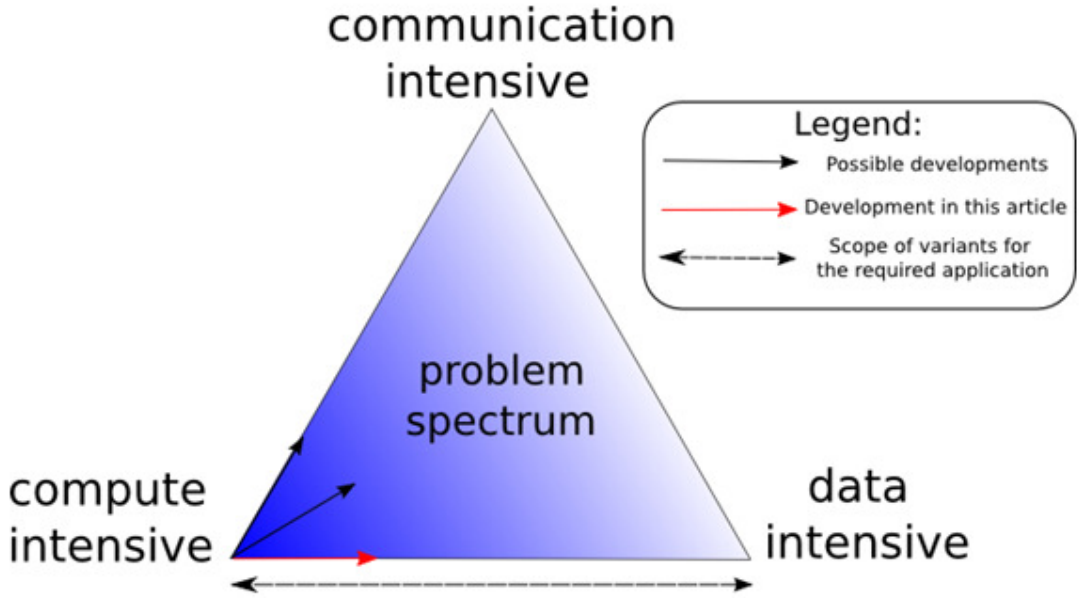

Figure 1. Spectrum of Computational Problems from the Parallelization Viewpoint

The black arrows on Figure 1 show possible directions of development of the KernelHive system. Moving in the direction towards communication intensive vertex of the problem spectrum, we would be dealing with applications that require communication between the processes (for example for frequent updating intermediate results). This direction of development should be addressed in the future.

In this paper we follow the red arrow and add data intensity flavor to the KernelHive system. For this purpose, we propose an architecture of distributed databases and a versatile protocol, that allows using various database systems. In order to show the possibilities of this architecture, using the exchangeable optimizer API in KernelHive and MongoDB for storage, we implement a data prefetching optimizer.

3. PROPOSED SOLUTION

3.1. Overview of the Existing Architecture

The system architecture so far is shown on Figure 2. Using the graphical interface, the user defines an application in a form of a directed acyclic graph. Graph nodes correspond to computational tasks and are selected from a repository of predefined node types (e.g. processor, partitioner, merger). Each node is provided with a number of computational codes corresponding to its role. The edges of the graph denote the direction of data flow between the tasks.

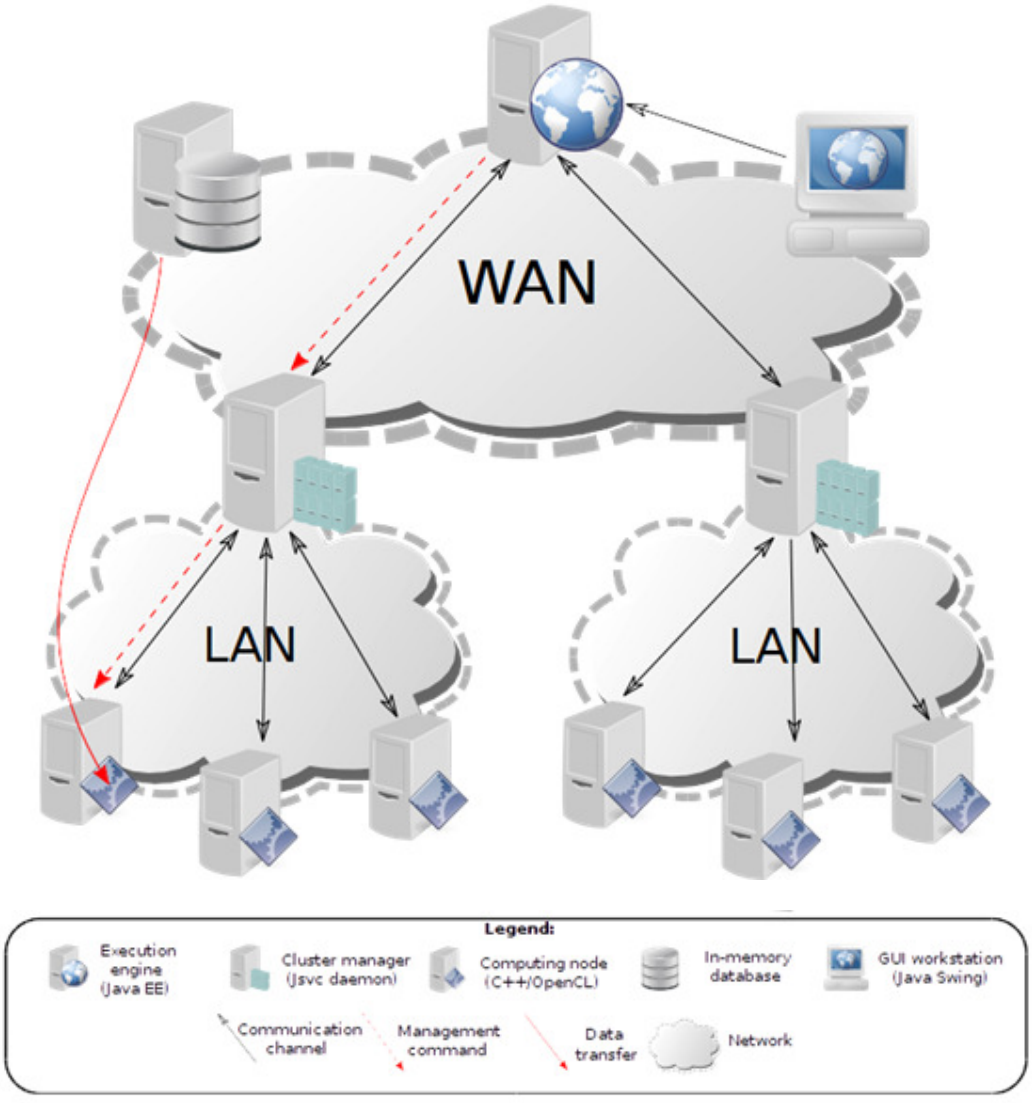

Figure 2. Basic Architecture of the Parallel System

Applications for the system can be defined using our graphical tool called *hive-gui* (Java Swing application), however they are represented in a XML format, allowing other front-ends to use the parallel system. A tested example of such front-end is the Galaxy Simulator [9] which was

extended by a plugin for KernelHive executions. The application XML, along with data addresses are dispatched to execution by a SOAP web service.

Analysis and deployment of the applications is performed by the *Engine*, which is a high-level Java application. All of the subject modules report their state to the engine, keeping a live representation of the whole system in the engine. Thus we can define rules of scheduling the tasks that have a rich view of the available infrastructure and its state.

One of the distinct features of KernelHive is that it is designed to combine multiple distributed clusters. The only requirement towards a cluster is that there should be one machine playing a role of an entry point to the cluster, which has to be visible (in terms of network) by the *Engine*. To address this requirement, the system utilizes the *Cluster* subsystem, working as a Java system daemon.

The cluster manager is a middleman between the engine and computing devices, which are managed by C++ daemons, capable of dynamic compiling and running OpenCL [10] computational code.

3.2. Novelty

In the embarassingly parallel applications considered so far, the time of sending the input data to the computational node was negligible: the data could be considered as a part of the management command and stored in memory. However, in case of larger data a method of storing data on hard drive has to be employed, should it be a database system or file system. What is more, it should be noted that the bandwidth between the cluster manager and engine and, more importantly, data server, is significantly lower than in the local network between cluster manager and computational nodes. In case of larger input data, we propose an approach, where management commands contain only addresses of data packages. The addresses are defined in a versatile way and consist of:

- hostname – the TCP hostname of the data server
- port – the TCP port of the data server
- ID – identifier of the data package unique within the data server scope

This approach has two main advantages:

- tolerates different technologies for the data servers, which allows to adjust the data server to the characteristics of given application and deployment
- grants the possibility to move the data between the servers during the application runtime and changing the addresses in management commands at low cos

In this paper we show examples of exploring both these advantages. For the first one, we propose using MongoDB key–value store with the GridFS [11] drivers as the technology for data servers. The power of the second advantage is exposed on the example of communication and computation overlapping by prefetching input data to local servers. The modified architecture of the system is depicted by Figure 3.

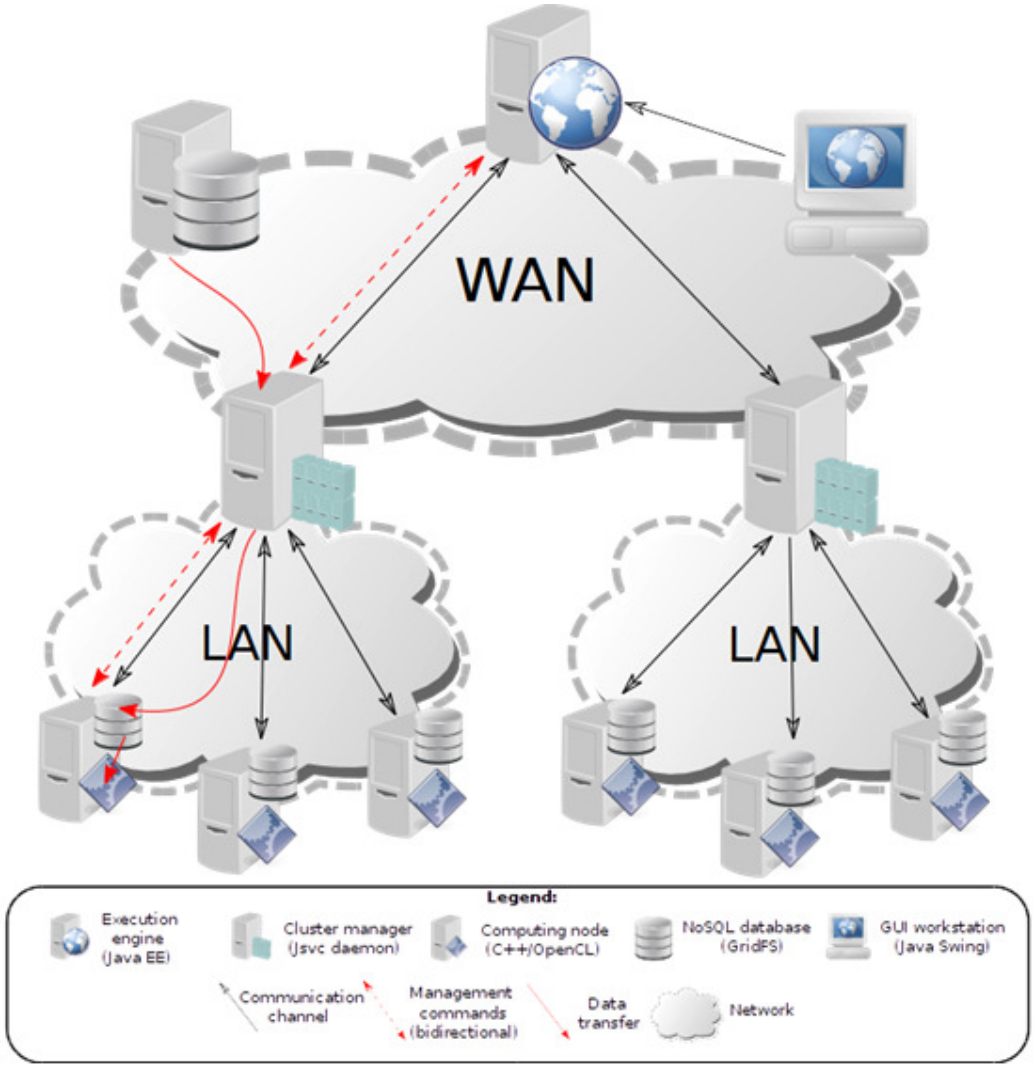

Figure 3. Modified Architecture of the Parallel System

3.3. NoSQL Data Servers

There are numerous technologies designed for storing and accessing big data. The concept of file systems evolved from basic structures for storing data on local hard drives to sophisticated distributed file systems. These solutions are closely connected with the operating system issues, like access control and hierarchical organisation of data. Because of this, they often introduce some constraints on file names, limit number of files in a directory etc. However, file systems are widely used as the backend for HPC systems, which have to be aware of the characteristics of used file systems.

Another important approach towards storing data is relational databases. Database management systems (DBMS) deal with the low level details of storage and hide them from the user. They provide wide functionality of storing, retrieving, filtering data, often with regard to transactions and cascading of operations. The data is modeled in a rigid form of relational tables with columns corresponding to certain object attributes and rows representing some objects.

In case of HPC systems, we rarely require the database to understand the model of our data. Often, we just need to store a big file and keep an address to refer to it later. However, we would like to benefit from the low–level internal transparency offered by the database systems. For this reason, we propose to use a NoSQL database for our reasons.

The NoSQL [12] concept is close to the relational databases, however abandons the rigid representation of data. For our experiments, we chose the most popular NoSQL database at the time, MongoDB. This database system comes with an extension called GridFS. The extension is actually a functionality of the MongoDB drivers that allows automatic dividing the data to chunks, storing them separately, but keeping information about the whole files in metadata.

Another reason for using MongoDB in our heterogeneous system is that it offers mature driver implementations for different programming platforms. We benefited from the implementations in:

- python – for the input data package generator
- C++ - for the program on the computing devices to download the input database
- Java – for the cluster manager to perform the data prefetching

3.4. Data Prefetching

The KernelHive *Engine* defines a IOptimizer programming interface, listed in Figure 4.

```
public interface IOptimizer {
        /**
         * Given a submitted workflow and available infrastructure,
         * return a list of scheduled jobs with assigned devices to
         * be deployed by the Engine.
         */
         public List<Job> processWorkflow(Workflow workflow, Collection<
              Cluster> infrastructure);

}
```

Figure 4. *IOptimizer* interface

The input of each Optimizer implementation consists of:

- *Workflow* – class representing the whole application workflow, including individual jobs and relations between them. The optimizer has access to the state of each job (e.g. pending, ready, prefetching, prefetching finished, finished)

- collection of *Clusters* – a set of instances of *Cluster* class, each representing a collection of computational nodes. The optimizer has access to the full infrastructure model, including the computing devices, their characteristics and current state.

The value returned by the optimizer is a list of jobs, that were scheduled for execution. Additionally, the optimizer should change the states of affected jobs and devices.

The interface is general enough to allow its implementations to focus on different criteria and perform diverse tasks. It is also possible to combine several optimizers to achieve a complex goal. We have already implemented scheduling optimizers aimed for dynamic assignment of jobs that

became ready for execution to available devices according to certain criteria (e.g. performance, energy efficiency).

The new *PrefetchingOptimizer* implementation requires an internal optimizer for scheduling. This way, choosing the hardware for computations can be done by an exchangeable component. Such base is extended by a data prefetching mechanism, listed in Figure 5. The optimizer implementation keeps the information about currently performed prefetchings in a map. Each prefetching process is represented by a key-value pair of jobs:

- key – a job that is being processed (data has already been downloaded by the worker)
- value – next job assigned to the same computational device as the key job, however not yet scheduled for execution – only for data downloading

Using a data structure defined this way, the tasks of the optimizer are as follows:

- if a key job has ended and the prefetching for the corresponding next job is over, mark the latter as scheduled for execution
- let the internal optimizer perform the scheduling of jobs that became ready for execution (due to the workflow dependencies) using hardware that became available (because it finished its computations or has been just connected to the system)
- ensure, that for each currently processed job, there is a corresponding job, for which the input data is being prefetched (provided there are some jobs ready for execution)

The optimizers *processWorkflow* method is called by the *Engine* upon every event that changes the aforementioned states of jobs and hardware, including finishing a job, finishing a prefetching, submitting new workflow or connecting new hardware.

After each call of this method, the list of scheduled jobs returned by the optimizer is sent by the *Engine* to appropriate *Cluster* subsystem instances. Then, the jobs are forwarded to the assigned machines, where the *Unit* subystem listens for jobs to run. Finally, the adequate *Worker* binary is executed. It downloads the necessary input data, application code, builds it and runs the computations.

When the computations are finished, the output data is saved in a previously configured database. A management command is send back through the *Cluster* to the *Engine*, containing the resulting data package ID. In case of final results, the ID is used to download them upon users request. In case of intermediate data, the ID is used by following jobs in the workflow.

```
public class PrefetchingOptimizer implements IOptimizer {

        private Map<EngineJob, EngineJob> prefetchingMap = new HashMap<EngineJob, EngineJob>();
        private IOptimizer baseOptimizer;

        public PrefetchingOptimizer(IOptimizer baseOptimizer) {
                this.baseOptimizer = baseOptimizer;
        }

        @Override
        public List<Job> processWorkflow(Workflow workflow,
                        Collection<Cluster> infrastructure) {
                // First schedule jobs that were prefetched
                List<Job> scheduledJobs = schedulePrefetchedJobs();

                // Then schedule jobs to free resources
                scheduledJobs.addAll(baseOptimizer.processWorkflow(workflow, infrastructure));

                // Then start prefetchings
                List<EngineJob> processingJobs = workflow.getJobsByState(Job.JobState.PROCESSING);
                processingJobs.removeAll(prefetchingMap.keySet());

                if(processingJobs.size() > 0) {
                        List<EngineJob> readyJobs = workflow.getJobsByState(Job.JobState.READY);
                        Iterator<EngineJob> readyIterator = readyJobs.iterator();
                        for(EngineJob pj : processingJobs) {
                                if(!readyIterator.hasNext())
                                        break;

                                EngineJob prefetchingJob = readyIterator.next();

                                prefetchingJob.device = pj.device;
                                prefetchingJob.runPrefetching();

                                prefetchingMap.put(pj, prefetchingJob);
                        }
                }

                return scheduledJobs;
        }

        private List<Job> schedulePrefetchedJobs() {
                List<Job> scheduledJobs = new ArrayList<Job>();
                List<EngineJob> toRemove = new ArrayList<EngineJob>();
                for(EngineJob processingJob : prefetchingMap.keySet()) {
                        if(processingJob.state == JobState.FINISHED) {
                                EngineJob prefetchingJob = prefetchingMap.get(processingJob);
                                if(prefetchingJob.state == JobState.PREFETCHING_FINISHED) {
                                        prefetchingJob.schedule(prefetchingJob.device);
                                        scheduledJobs.add(prefetchingJob);
                                        toRemove.add(processingJob);
                                }
                                // Do not schedule new job if we are waiting for prefetching
                                else prefetchingJob.device.busy = true;
                        }
                }

                for(EngineJob tr : toRemove)
                        prefetchingMap.remove(tr);

                return scheduledJobs;
        }

}
```

Figure 5. The new *PrefetchingOptimizer*

4. EXPERIMENTS

The proposed solution was tested in one series of experiments. We measured the execution times of a regular expression matching application with different numbers of input data packages. The data packages are 20MB files of random characters, generated and stored in MongoDB by our generator script. Additionally, each package is prefixed with a header containing the needle and haystack sizes, and the needle itself. In the experiments we searched for the occurrences of the pattern ”a*b*c*d”.

The prefetching algorithm should enhance the systems performance provided the WAN network shown on Figure 3 brings significant delays and bandwidth limits. To reflect this situation during the experiments, the source database was hosted on a server in France, while the computations took place in our department lab in Poland.

4.1. Experiments on a Single Device

We started with testing the solution on a basic setup with one machine equipped with one Intel Core i5 processor. The execution times in seconds were gathered in Table 1. As it turns out, the results in case of a single device are as expected: for one data package, the difference between execution time with and without prefetching is negligible. The scenario of execution is the same in both cases. The more data packages, the higher the speedup of the prefetching version, reaching 30% in case of 4 input packages. The difference is significant and increasing, because in the prefetching scenarios, data transmission and computations are overlapping.

Table 1. Results of the Single Device Experiment

NPackages	No prefetching	Prefetching
1	28s	29s
2	60s	54s
3	91s	63s
4	123s	86s

4.2. Experiments on a Heterogeneous Infrastructure

After testing the proposed design in action and proving the usefulness of the prefetching optimizer, we tested the same application on a cluster of nodes equipped with different types of devices. The infrastructure for this extended tests is shown on Figure 6, which is actually a screenshot from the hive-gui application, that enables generating the infrastructure charts based on the data from the *Engine*.

In order to compare the results in the new testbed configuration to the previous ones, we had to run the application with package numbers N times higher, where N is the number of computing devices.

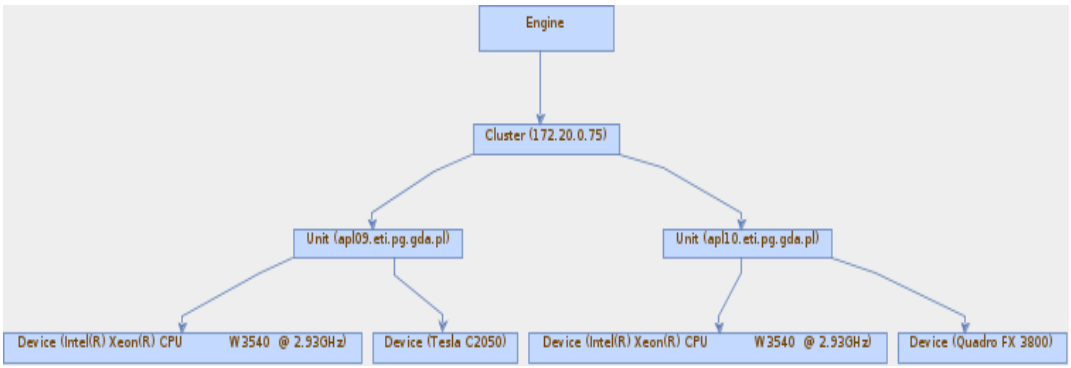

Figure 6. The Heterogeneous Testbed Configuration

The results of the experiment (Table 2) show, that the benefit from prefetching, though significant and increasing, is lower than for one device and in case of 4□n packages reaches 11%. Such results could be an effect of sharing the network between multiple prefetching tasks. Still, the optimizer shows promising results in a heterogeneous environment.

Table 2. Results of the Heterogeneous Environment Experiment

NPackages	No prefetching	Prefetching
4	31s	32s
8	77s	66s
12	87s	73s
16	103s	91s
20	122s	104s

5. SUMMARY AND FUTURE WORK

Focusing on the aspect of data management in parallel computing systems brings up a number of issues, especially in case of heterogeneous multi–level systems. In this paper we addressed a subset of those issues by extending our parallel framework KernelHive.

We proposed an architecture with multiple distributed data servers and a versatile data addressing scheme that enables using various data storage technologies and high–level optimizations. On this basis we used GridFS as a data storage engine and presented the implementation of a new optimizer for KernelHive, that enables prefetching data to the computing devices, causing the overlapping of computations and communication.

Our experiments, based on a regular expression matching application showed that the proposed solution is a base for new data management schemes. In the future we could extend this solution by mechanisms of dynamic transferring of intermediate results between the parallel processes with regard to their distribution, possibly among distant clusters.

ACKNOWLEDGEMENTS

The work was performed partially within grant “Modeling efficiency, reliability and power consumption of multilevel parallel HPC systems using CPUs and GPUs” sponsored by and covered by funds from the National Science Center in Poland based on decision no DEC-2012/07/B/ST6/01516.

Special thanks to Tomasz Boiński (http://tboinski.eti.pg.gda.pl) for his invaluable support.
